Summary

Avian cryptosporidiosis has been reported in more than 30 species of birds. To date, the species infecting birds are C. baileyi, C. galli and C. meleagridis. In this study, the prevalence of Cryptosporidium in southern Iran and the morphological characteristics of oocysts are described. Cryptosporidium oocysts were found in the faeces of 21 of 75 examined ostriches (28%) from 3 farms in southern Iran. The genus identity of the oocysts was confirmed by morphology. The mean (±SD) size of 102 oocysts was 4.4±1.14 × 3.9±0.96 µm (range 3.8–8.6 × 2.9–7.6 µm) with a shape index (length/width) of 1.13±0.13 (range 1.0–1.33). Data analyses indicated no significant effect of ostrich population on the prevalence of Cryptosporidium infection. Based on the odds ratio, an increase of 1 m² space for each ostrich decreased the prevalence of disease by a factor of 0.99. Stressing conditions leading to immunosuppression or poor husbandry practices related to feed, water or hygiene, were apparently acting as predisposing factors to the onset of cloacal prolapse or other pathology related to the Cryptosporidium spp. found in this experiment, since the improvement in husbandry practices has stopped the mortality and clinical signs, even in the presence of the parasite. To our knowledge, this is the first report of Cryptosporidium spp. occurrence in ostriches in Iran.

Key words: Cryptosporidium spp., Iran, morphology, ostriches

INTRODUCTION

Protozoa of the genus Cryptosporidium are apicomplexan parasites that complete their biological cycle in the surface of epithelial cells of the digestive and respiratory systems of a wide variety of vertebrates (Xiao et al., 2004). Once considered rare and irrelevant, Cryptosporidium spp. are now known to be important pathogens, with a widespread distribution in livestock, wildlife, and humans (Fayer, 2004). Transmission is through the faecal-oral route, following direct or indirect contact with Cryptosporidium oocysts via animal-to-animal, waterborne, foodborne or airborne contact (Fayer, 2004). Cryptosporidiosis has been reported in more than 30 species of birds in many countries (Lindsay & Blagburn, 1990a; Sréter & Varga, 2000; Morgan et al., 2001). The parasite has been found in gastrointestinal, respiratory, urinary, pancreatic, and biliary tracts of hosts, and has been associated with disease (Gajadhar, 1993). Cryptosporidiosis is a significant cause of intestinal and respiratory tract disease in domestic chickens and turkeys (Fletcher
Epidemiology of Cryptosporidium infection in ostriches (Struthio camelus) in Iran

et al., 1975; Hoerr et al., 1978). Other avian species raised in confinement have also experienced severe disease caused by cryptosporidial infections of kidneys, nasal tissues, conjunctiva, intestine, and trachea (Goodwin, 1989; Palkovic & Pecka, 1989; Lindsay & Blagburn, 1990b). The infection in ostriches may be subclinical (Gajadhar, 1993) or associated to prolapse of phallus and cloaca (Allwright & Wessels, 1993; Bezuidenhout et al., 1993; Penrith & Burger, 1993; Penrith et al., 1994; Santos et al., 2005) and pancreatic necrosis (Jardine & Verwoerd, 1997).

In Europe, Cryptosporidium oocysts have been found in ostriches from Portugal, Netherlands, Belgium, France, Spain (Ponce Gordo et al., 2002), and Greece (Sotiraki et al., 2001). Iran is third only to South Africa and China in the world for ostrich breeding. The ostriches in Iran are mostly imported from Spain, Belgium, South Africa and Australia.

So far, there is no reports on the occurrence of Cryptosporidium in ostriches (Struthio camelus) in Iran. This paper presents evidence of cryptosporidial infection in this species, the prevalence and morphological characteristics of Cryptosporidium in ostriches, reared in southern Iran.

MATERIALS AND METHODS

Farms evaluation and sampling

Out of 6 ostrich farms in Shiraz, southern Iran (29°50′N, 52°46′E and an altitude of 1630 m), 3 farms that had high morbidity rates of diarrhoea of unknown origin, recorded from 1 month to 4 years ago, were selected.

At least one freshly passed individual faecal sample was obtained from 75 of 350 ostriches (25 samples of each farm) (Table 1). The entire stool samples were examined as wet smears for detection of helminthic ova and larvae; then precipitated and stained by Giemsa and modified Ziehl-Neelsen technique for detection of Cryptosporidium oocysts.

Case history

A female 2.5-month-old ostrich (Struthio camelus) from an ostrich rearing farm with cloacal prolapse was examined. The bird had a history of poor nutrition, diarrhoea, repeated antibiotic therapy, overcrowding and a contaminated environment. Faecal sample was collected aseptically, and submitted for parasitological and bacterial screening. No pathogenic bacteria were detected in the culture. The faecal sample was stained by Giemsa and modified Ziehl-Neelsen technique. Oocysts of Cryptosporidium were found. The bird died after 2 hours because of severe dehydratation.

Morphological analysis

The size and morphology of the oocysts were determined by evaluating 102 oocysts with an Olympus BX-45 microscope equipped with a calibrated ocular eyepiece micrometre.

Statistical analysis

The data were analyzed with the chi-square test. Values of P<0.05 were considered significant. The variables possibly affecting the prevalence of Cryptosporidium infection are listed in Table 1. The population of ostriches in the third herd (250) was used as reference. The data from each herd were compared by logistic regression analysis using the prevalence rates as the dependent variable and population and density as independent factors. The factor population of ostriches was coded as a class variable. Density of os-
triches was considered as continuous variables.

Regression analyses were conducted according to the method of Hosmer & Lemeshow (1989) by the logistic procedure of the SPSS package (SPSS for Windows, version 11.5, SPSS Inc, Chicago, Illinois). Basically, this method involves five steps as follows: preliminary screening of all variables for univariate associations; construction of a full model using all the variables found to be significant in the univariate analysis; stepwise removal of non-significant variables from the full model and comparison of the reduced model with the previous model for model fit and confounding; evaluation of plausible two-way interactions among variables and assessment of model fit using Hosmer–Lemeshow statistics. Variables with univariate associations showing \( P<0.25 \) were included in the initial model. We continued modeling until all main effects or interaction terms were significant according to the Wald statistic at \( P<0.05 \).

**RESULTS**

No helminthic ova and larvae were found in wet smears. Oocysts were found in the faeces from 21 of 75 ostriches (28%), out of which 10 (40%) cases were in farm 1, 4 (16%) in farm 2 and 7 (28%) in farm 3 (Table 2).

102 oocysts of *Cryptosporidium* in ostriches measured 3.8–8.6 × 2.9–7.6 µm (mean ± SD 4.4±1.14×3.9±0.96 µm) with a shape index (length/width) of 1.0–1.33 (mean± SD 1.13±0.13) (Table 3). Oocysts contained four sporozoites that were seen by Nomarski interference (Fig. 1).

Logistic regression analyses indicated no significant effect of ostrich population size on the prevalence of *Cryptosporidium* infection. Table 4 shows the odds ratio of the variable included in the final logistic regression model. Based on the odds ratio, the increase of 1 m\(^2\) space for each ostrich decreases the prevalence of disease in ostriches by a factor of 0.99.

DISCUSSION

To our knowledge, this is the first report of Cryptosporidium in ostriches in Iran. Natural infections of Cryptosporidia are widespread among birds and have been associated with disease (Goodwin, 1989; Lindsay & Blagburn, 1990b). The number of distinct species of Cryptosporidia that can infect birds is unknown. This is due to uncertainty about the extent of host range of Cryptosporidia found in a variety of birds.

The Cryptosporidia are important from economic and sanitary points of view. There are some references to Cryptosporidium spp. prevalence in ratites; all of them are from ostriches only, although this parasite has been found by Ponce Gordo et al. (2002) in rheas as well. In ostrich chicks, it has been indicated as the cause of phallus and cloacal prolapse (Bezuidenhout et al., 1993; Penrith & Burger, 1993; Penrith et al., 1994), enteritis (Huchzermeyer, 1999) and pancreatic necrosis (Jardine & Verwoerd, 1997). Clinical illness was not observed in any of the adult ostriches where cryptosporidial oocysts were isolated. Gajadhar (1994) described the presence of oocysts related to the occurrence of subclinical cryptosporidiosis in adult ostriches. However, as with C. parvum, C. meleagris, and C. baileyi (Goodwin, 1989, Fayer et al., 1990; Lindsay & Blagburn, 1990b), it is possible that the present Cryptosporidium spp. of ostriches causes disease in young ostriches and birds that are immunocompromised or infected with other agents. The occurrence of fatal disease when cryptosporidiosis was associated with secondary bacterial or viral infection has been reported (Current, 1985). It appears that adult ostriches are susceptible to patent cryptosporidial infection, and...
may be a source of infection for young and immunocompromised birds.

Stressing conditions leading to immunosuppression or poor husbandry practices related to feed, water or hygiene could appear as predisposing factors to the onset of cloacal prolapse or other pathology related to the *Cryptosporidium* infection observed in this study. Based on the odds ratio, the increase of 1 m² space for each ostrich decreased the prevalence of disease in ostriches by a factor of 0.99, since the improvement in husbandry practices has stopped the mortality and clinical signs, even in the presence of the parasite. Therefore, this implies that high population density (overcrowding) could have been the most important predisposing factor for development of disease in ostrich farms with the group size used in the present study.

The species of *Cryptosporidium* that infect ostriches are still undetermined. Some authors consider it could be a new species, whose oocysts are similar in size to those of *C. meleagridis* (6–8 µm) (De Graaf et al., 1999, Morgan et al., 2001). Besides this species, and according to the size of the oocysts we have found, a second species whose oocysts are of the same size as those of *C. parvum* (3–5µm) was also involved and its prevalence was higher.

Some oocysts of the Iranian isolate are similar to those of *C. meleagridis* found in ostriches by Gajadhar (Gajadhar, 1994) are related to *C. meleagridis*, which is spherical and measures 5.2×4.6 µm; and has a shape index 1.13 (Lindsay et al., 1989), and not to *C. baileyi* whose oocysts have an ovoid shape and measure 6.0×4.6 µm; shape index 1.31 (Meireles & Figueiredo, 1992) or 6.3×5.2 µm; shape index 1.4 (Current et al., 1986) and that is similar to the morphological data of the Brazilian ostrich isolate, 6×4.8 µm; shape index 1.31 (Santos et al., 2005).

For a definitive classification of this isolate as *C. baileyi* or as a new species infecting ostriches, a comparison of the sequenced fragments would be necessary, followed by phylogenetic analysis. Besides, further studies on its biological and morphological characteristics would also be necessary. Avian genotype II isolates were identical to a novel *Cryptosporidium* genotype recently identified in ostriches (Meireles et al., 2006, Ng et al., 2006).

The adequate identification of these organisms should be achieved after application of biochemical and molecular techniques. A detailed description of the parasite and further taxonomic studies will be reported separately.
